Supporting Information

ABSTRACT: Surface charging is an often overlooked factor in many plasma–surface interactions and in particular in plasma catalysis. In this study, we investigate the effect of excess electrons induced by a plasma on the adsorption properties of CO$_2$ on titania-supported Cu$_5$ and Ni$_5$ clusters using spin-polarized and dispersion-corrected density functional theory calculations. The effect of excess electrons on the adsorption of Ni and Cu pentamers as well as on CO$_2$ adsorption on a pristine anatase TiO$_2$(101) slab is studied. Our results indicate that adding plasma-induced excess electrons to the system leads to further stabilization of the bent CO$_2$ structure. Also, dissociation of CO$_2$ on charged clusters is energetically more favorable than on neutral clusters. We hypothesize that surface charge is a plausible cause for the synergistic effects sometimes observed in plasma catalysis.

INTRODUCTION

Plasma catalysis$^{1,2}$ holds promise for many environmental$^{3–8}$ and industrial$^{9,10}$ applications. Combining a plasma with a catalyst induces a complex reciprocal interaction, which in some cases leads to synergistic effects that improve the efficiency of the catalytic reactions. However, the underlying reasons for the synergy in plasma catalysis remain unknown. Reaction promotion in the catalytic removal of NO$_2$, higher CO$_2$ conversion,$^{11}$ decrease in the energy barrier for dry reforming of methane,$^{12}$ and increased treatment efficiency on Escherichia coli cells in aqueous media$^{13}$ have been reported as a result of synergistic effects in plasma catalysis.

Plasma is an ionized gas that consists of different interacting species such as electrons, ions, neutral atoms, and vibrationally and electronically excited species. The presence of these species makes the plasma a highly reactive but nonselective environment that is very suitable for combining with a catalyst.$^2$ In particular, the plasma leads to a modification of the gas phase (and hence the reactants), while still allowing for a (relatively) low temperature. The contribution of all of the specific plasma factors strongly depends on the type of plasma and the working conditions and has been studied extensively. The mechanisms of plasma-induced changes in the structural and electronic properties of the catalyst remain largely unresolved. To unravel (some of) the mechanisms underlying plasma–catalyst interactions, we need to narrow down the complexity of the system by focusing on a specific factor and its effect on the whole plasma–catalytic process. Complementary to experiments, computer simulations are ideally suited for this.

A catalyst surface becomes inevitably charged upon interaction with a plasma. The accumulated surface charge can alter the electronic and geometric structures of the catalyst, consequently leading to a change in the kinetics of the whole catalytic reaction. Even changes in the activity of the different geometric structures of a catalyst are generally ascribed to differences in their electronic structures.$^{15}$ Hence, by considering the electronic properties of the catalyst during its interaction with a plasma, one can gain information about the effect of plasma-induced surface charging on catalytic reactions.

The effect of surface charging, for instance due to a plasma, is important in heterogeneous catalysis and in particular when transition metal clusters are deposited on oxide surfaces. Excess electrons accumulated on the oxide surface can alter the electronic structure and adsorption properties of the supported transition metal nanoparticles. Although there have been experimental$^{16,17}$ and theoretical$^{18,19}$ investigations on the effect of plasmas in heterogeneous catalysis, and studies have been carried out on the deposition of metal clusters on oxide surfaces without a plasma,$^{20–22}$ the effect of plasma-induced excess electrons on the deposition of metal clusters and their catalytic properties has been scarcely investigated. Both nickel
and copper are widely used in heterogeneous catalysis, for instance, for CO₂ conversion for forming value-added products like methanol. We here choose to study Ni and Cu pentamers. First, these clusters can be synthesized and are actually used in the catalysis community. Further, because of their small size, they require less material, making them cheaper (per unit surface area) and possibly more environmentally friendly. Finally, considering the limited number of possible isomers, their fluxionality (in gas phase) is much lesser than that of larger clusters, which makes them computationally tractable.

In this study, we report the role of excess electrons in (1) the adsorption of Ni₅ and Cu₅ clusters on an anatase TiO₂(101) slab as test systems, (2) the adsorption of an adsorbate molecule (CO₂) on the stoichiometric surface of anatase TiO₂(101), (3) the adsorption of a CO₂ molecule on TiO₂-supported Ni₅ and Cu₅ clusters, and (4) the dissociation of the CO₂ molecule.

As a reducible oxide, TiO₂ is an interesting candidate to investigate the effects of surface charging. Among the various polymorphs of titania, anatase has been widely used in modeling catalytic reactions. The (101) plane of anatase (α-TiO₂) has been chosen for the adsorption of the metal clusters because of its high thermodynamic stability.24

## COMPUTATIONAL DETAILS

All calculations have been carried out based on the spin-polarized density functional theory (DFT) by using the Quickstep27 module of the CP2K package. This module mainly employs localized Gaussian orbitals and auxiliary plane waves as a dual basis for expanding the Kohn−Sham orbitals. Double-$\zeta$ valence plus polarization basis sets, which are optimized from molecular interactions (MOLOPT),29,29 combined with a plane wave basis set with 800 Ry cutoff have been used for the calculations. Goedecker−Teter−Hutter pseudopotentials30,31 are used for describing the inner shell electrons; for C, O, Cu, Ti, and Ni atoms, 4, 6, 11, 12, and 18 valence electrons are explicitly considered, respectively. The general gradient approximation Perdew−Burke−Ernzerhof32 functional is applied for treating electron exchange and correlation effects. Dispersion interactions are included through Grimme’s D3 approximation along with Becke−Jonsson damping.33,34 The Broyden−Fletcher−Goldfarb−Shanno scheme is used for geometry optimization where a maximum force of 0.02 eV/Å has been set for the relaxation of atoms. The k-point sampling is limited to the Γ-point only, and the Hirshfeld-I scheme35 is used for charge analysis of interactions between the adsorbates and the slab surface.

Lattice parameters of bulk anatase TiO₂ ($a = b = 3.7845$ Å and $c = 9.5143$ Å)36 were used for creating the surface slabs. A slab of anatase (101) with dimensions of $10.239 \times 11.3535 \times 3.00$ Å$^3$ (1 × 3 supercell) consisting of six O−Ti−O trilayers and containing 108 atoms (Figure 1) was used for the calculations. To mimic the bulk-like structure, we fixed the bottom layers of the support in a first set of calculations. This, however, also leads to interference in the excess electrons’ localization pattern. Thus, we also examined a fully relaxed structure, with no atoms frozen. The results with the fixed layers are mainly provided in the Supporting Information (S1); we here mainly focus on the results achieved without applying any constraint on the relaxation of the atoms. Calculations for the metal clusters and the CO₂ molecule in gas phase have been carried out in a box of 15 × 15 × 15 Å$^3$ dimensions.

For the treatment of charged configurations, we applied our recently proposed method37 suitable for modeling plasma−surface interactions. In this approach, we use a positive countercharge located far from the surface (in the z-direction) without assigning a local basis set to it. Thus, the electron density is not allowed to be distributed around the ion, but rather it will be localized on the surface. This is an ideal approach for modeling the effect of plasma-induced excess electrons on the surface of a catalyst, because it explicitly incorporates both the negative charging from excess electrons as well as polarization effects and electric fields arising from positively charged ions in the plasma sheath region in the gas phase.

Electrostatic interactions were described with the Martyna−Tuckerman (MT) Poisson solver,38 which requires the z-component of the cell size to be very large (100 Å) for charged configurations. The MT solver allows one to impose full periodicity along the surface slab (in the xy plane), mimicking a semi-infinite catalyst surface, while simultaneously removing periodicity along the z direction. As such, unphysical interactions of the slab with itself are avoided, which would otherwise result in significant computational artifacts when dealing with charged surfaces.39

We employed DFT + $U$40,41 calculations for cross-checking the results, while accounting for the strong onsite Coulomb interactions. By using this approach, the self-interaction effect for Ti d-orbitals will be corrected by Hubbard’s $U$ parameter. This parameter is set to 5 eV for Ti atoms. Considering the small number of atoms in clusters studied in this work, and negligible impact of their self-interaction on the results, no Hubbard parameter is applied to the d-orbitals of Ni and Cu atoms. Considering that DFT + $U$ provides a better picture for electron localization on support cations, we referred to the projected density of states (PDOS) and spin density diagrams obtained by the DFT + $U$ calculations.

We investigated the effect of charge in two ways: First, reoptimization of the neutral structure after adding an excess electron to the system, and second, optimization of the initially negatively charged configuration. After finding the most stable mode for both neutral and charged configurations, we made a comparison between the corresponding adsorption energies and other properties for the neutral and negatively charged structures.
Adsorption energies of clusters on anatase are calculated based on eq 1, where $E_{\text{cluster}}$ is the total energy of the Ni$_5$/Cu$_5$ clusters, $E_{\text{slab+cluster}}$ is the total energy of the complex (consisting of cluster and surface), and $E_{\text{slab}}$ is the total energy of the bare slab.

$$E_{\text{adsorption}} = E_{\text{slab+cluster}} - E_{\text{cluster}} - E_{\text{slab}}$$

(1)

Similarly, the adsorption energy of CO$_2$ on the supported cluster is calculated as follows:

$$E_{\text{adsorption}} = E_{\text{complex+molecule}} - E_{\text{complex}} - E_{\text{molecule}}$$

(2)

Thermal and zero-point energy calculations are not considered.

## RESULTS AND DISCUSSION

### Adsorption of Ni$_5$ and Cu$_5$ Clusters on the Anatase (101) Surface.

To investigate the adsorption of Cu$_5$ and Ni$_5$ on the TiO$_2$ surface, we first optimized their structures in the gas phase, as described in the SI. Then, the clusters were deposited on the neutral anatase (101) surface and their adsorption energies were calculated. Subsequently, one electron was added to this configuration, and the system was reoptimized. This allowed us to compare the adsorption properties of each metal cluster in the neutral and charged systems. Similar to the gas phase calculations, we explored five initial structures with different orientations of the cluster adsorbing on the surface. Then we examined the most stable orientation in five different adsorption sites. The most stable configurations found for the adsorption of Ni$_5$ and Cu$_5$ clusters are shown in Figure 2, whereas the unstable adsorption modes are provided in the SI. We acknowledge that this procedure does not guarantee finding the global minimum.

Upon adsorption, hardly any change in the shape of the Ni$_5$ cluster is seen. Adsorption of the Ni$_5$ cluster on the anatase surface changes the electronic structure of the support such that the Ni d-orbitals fill the band gap of the TiO$_2$ semiconductor (see the SI) in agreement with the literature. Population analysis based on the Hirshfeld scheme shows that during the adsorption of Ni$_5$, there is a charge transfer from the support to the cluster. For the gas phase Ni$_5$ cluster, the total spin moment ($n_\alpha - n_\beta$) is 2 $\mu_B$ (triplet state), which changes to 3.1 $\mu_B$ upon adsorption. Also, the accumulated net charge of $-0.893$ e on the Ni$_5$ cluster shows that there is a significant charge transfer between the cluster and the surface, which leads to a high adsorption energy of $-5.72$ eV. This electron transfer from the support to the cluster leaves the support with one unpaired electron as can be seen from the spin density isosurfaces (Figure 3a).

Upon adsorption, the Cu$_5$ cluster changes its original planar configuration to a more three-dimensional structure, facilitating strong interaction between the cluster and the oxide surface with an adsorption energy of $-4.29$ eV. In comparison with Ni$_5$, the d-orbitals of the Cu$_5$ cluster partially lie in the TiO$_2$ band gap with a tendency to be located near the valence band (see the SI). The charge transfer direction between the support and the cluster is different for Ni$_5$ and Cu$_5$. The Cu$_5$ has a total spin moment of 2 $\mu_B$ (doublet state) in the gas phase, which changes to 0 after its adsorption on the support surface. During the adsorption, one unpaired electron in the Cu$_5$ cluster is transferred to the support. From Figure 3c, we can see that the transferred electron localizes on the subsurface Ti atom of the support.

After adding an excess electron to the relaxed neutral structures and reoptimizing, no change in the adsorption mode is seen. Changes in adsorption energies as described below can...
therefore (mostly) be attributed to the effect of the negative charge (Figure 4). Adding a single excess electron to the

![Figure 4. Adsorption energies of Ni₅ and Cu₅ clusters on anatase TiO₂(101).](image)

surface model leads to an electron density of $8.6 \times 10^{17} \text{ m}^{-2}$ or a surface charge density of $-0.137 \text{ C/m}^2$, which is in the same order of experimental estimates of plasma-deposited charge densities on dielectrics and 4 times higher than that reported in recent particle-in-cell/Monte Carlo collision PIC/MCC simulations for plasma in contact with dielectric surfaces or catalyst pores.

From the spin density analysis (Figure 3b), we can see that for the charged Ni₅ structure, the added electron is mostly localized on the Ni cluster, changing its net charge to $-1.643$ lel and also the total net spin moment to $2.2 \mu_B$. This gives rise to a change in the adsorption energy of the cluster by $+0.06$ eV, amounting to an adsorption energy of $-5.66$ eV. However, in Figure 4, the DFT result without $U$ correction shows that when charging, the adsorption energy decreases by $-0.51$ eV, which is mostly because of the failure in localization of the excess electron.

In contrast, upon negatively charging the surface, no spin polarization on the Cu₅ is seen, which means that the added electron is not localized on the cluster (i.e., the net spin moment of the cluster remains 0). Instead, as can be seen from Figure 3d, the presence of excess electrons leads to a change in the localization of the previously transferred electron. Eventually, two electrons are localized on the surface of the support, which decreases the adsorption energy by $1.20$ eV for the Cu₅ cluster, amounting to an adsorption energy of $-5.49$ eV. A detailed summary of the changes in the net spin moment and partial charges of the atoms for both neutral and charged structures is provided in the SI.

These results highlight the different effects of excess charge on the adsorption properties of Cu and Ni pentamers. Methodologically, these results also show that depending on the localization procedure of the excess electron, its effect on the stabilization of the adsorbed metal clusters can be different. Furthermore, it is seen that for fully relaxed systems, when using DFT calculations without considering onsite Coulomb interactions, it is difficult to describe the effect of excess electrons on the stability of the metal clusters.

**CO₂ Adsorption on Anatase TiO₂(101).** CO₂ adsorption on neutral anatase was previously studied by DFT. In this study, our aim is to investigate the effect of plasma-induced excess electrons on the adsorption of CO₂ on both the bare surface and on titania-supported Ni₅ and Cu₅ clusters. We will focus on the two most stable configurations for the adsorption of CO₂ on the anatase (101) surface, as shown in Figure 5.

![Figure 5. Most stable configurations for the linear and bent CO₂ structures adsorbing on the TiO₂(101) surface: (a) neutral and (b) charged configurations.](image)

We first kept the three layers of the TiO₂ slab frozen in their bulk structure to allow for a direct comparison between the results for neutral structures and the literature. For the linear configuration, CO₂ was found to adsorb on the neutral surface with adsorption energies of $-0.44$ and $-0.51$ eV using DFT and DFT + $U$, respectively. The bent structure shows an adsorption energy of $-0.03$ eV using DFT, whereas DFT + $U$ yields an adsorption energy of $-0.18$ eV. It can be seen that the results obtained using DFT + $U$ are in agreement with the values of $-0.48$ eV for linear and $-0.16$ eV for carbonate-like structures, as reported by Sorescu et al. and Iyemperumal et al. reported values of $-0.40$ and $-0.09$ eV for the most stable linear and bent structures, respectively. Results for both neutral and charged structures of CO₂ adsorption on bare TiO₂ (with fixed bottom layers) are shown in Figure 6a.

By removing the constraint on the bottom layers of the slab, the electron distribution is unbiased, which permits a reliable comparison between the neutral and charged structures. The results for fully relaxed systems are provided in Figure 6b. As we can see from this figure, the trends are maintained, although there are quantitative differences in the adsorption energies achieved for the system with fixed layers.

By adding charge to the system, both adsorption modes essentially maintain their structure. In the linear adsorption mode, the effect of excess charge on the adsorption energy is less pronounced. In this case, there is no mixing between the states of the molecule and the surface, such that the (small) increase in the adsorption energy of the linear CO₂ can be...
attributed to polarization effects. In this case, electrostatic Coulomb forces between the positive C atom and the negatively charged surface will lead to an improvement in the adsorption energy. The PDOS of the linear adsorption mode for both neutral and charged structures (Figure 7a,b) reveals that upon charging, the states of both oxygen atoms of the CO$_2$ molecule are shifted toward lower energies and this leads to a small improvement in the stabilization of the molecule.

For the bent structure, there is a substantial increase in the adsorption energy upon charging, to $-1.13$ and $-1.40$ eV in DFT and DFT $+U$, respectively, which is also reflected in the partial charges of CO$_2$ in the neutral and charged configurations: the partial charges on oxygen atoms of the CO$_2$ molecule change from $-0.862$ lel and $-0.624$ lel (neutral system) to $-1.028$ lel and $-0.728$ lel (charged system), respectively. Considering that the surface Ti atom bonded to the oxygen atom of the CO$_2$ molecule has preserved its net charge from the neutral configuration, we can see that the increase in adsorption energy is mainly due to the change in the partial charge of the molecule. This is consistent with the PDOS diagrams (Figure 7d) of the charged configuration, showing a shift in the DOS of the oxygen atoms of CO$_2$ toward the valence band, facilitating the pronounced mixing with orbitals of the surface Ti atoms, in comparison with the neutral case.

Table 1 shows the effect of charge on the adsorption energy of the two most stable modes of CO$_2$ on titania achieved by...
DFT and DFT + U. The same trend is clear from the results shown in Figure 6.

Transformation of the linear to the bent structure thus seems essential for CO₂ activation. It is clear from the results that adding a plasma-deposited excess electron to the system changes the most stable structure of the CO₂ adsorbed on titania surface from a linear to a bent configuration, which makes the activation of the CO₂ molecule thermodynamically more favorable. Correspondingly, we also analyzed changes in the C–O bond length and in the O–C–O bond angle as a result of negatively charging the surface. In Table 1, we summarize the results for the effect of charge on bond lengths and angles. It can be seen that the presence of excess charge has an impact on bending the CO₂ molecule, whereas the effect on the C–O bond elongation is limited.

CO₂ Adsorption on Supported Clusters. For the adsorption of CO₂ on titania-supported clusters, various initial modes were examined. In this case, we optimized each initial structure both with and without the presence of plasma-induced excess electrons.

Adsorption of CO₂ on the supported Ni₅ cluster does not lead to a marked change in the shape of the cluster. Bond formation between the CO₂ molecule and Ni atoms of the cluster results in a bent structure of CO₂ (Figure 8a) with adsorption energies of −0.53 and −0.31 eV using DFT and DFT + U, respectively. During CO₂ adsorption, the net spin moment of the cluster remains at 3 μ₀, whereas its net charge increases from −0.893 lel to −1.412 lel, indicating the formation of a polar covalent bond between the cluster and the C atom of the CO₂ molecule. The Ni atom that bonds to C has a net charge of −0.730 lel, whereas the carbon atom has a charge of 1.769 lel.

Adsorption of CO₂ on the supported Cu₅ cluster results in a noticeable change in the cluster shape. In this case, CO₂ adsors on the interface via the C atom making bonds with two copper atoms of the cluster and the oxygen atom with a surface Ti atom (Figure 8c). In this configuration, the Cu₅ cluster has three coordinations with surface oxygens and three with the CO₂ molecule, while maintaining a net spin moment of 0 and having a partial net charge of −0.205 lel. The net charges of the carbon and the two Cu atoms of the cluster are 1.502 lel, −0.064 lel, and −0.228 lel, respectively. This shows the formation of a covalent bond between the cluster and the CO₂ molecule.

Figure 9. Adsorption energy of the CO₂ molecule on Ni₅/Cu₅ clusters supported by anatase TiO₂(101).

The increase in the adsorption energy in case of the charged Ni₅ structure is mostly because of the extra bond formation between the C atom and the top Ni atom of the cluster (Figure 8b). Together with a net spin moment of 2 μ₀, the net charge on the cluster increases to −1.708 lel, explaining the stronger bond between the cluster and the (positively charged) C atom of the molecule. The PDOS reveals that upon charging, there is...
a shift in bonding states of the CO₂ molecule toward the valence band (Figure 10b). This leads to facilitation of the hybridization of high-lying CO₂ antibonding π* orbitals with d orbitals of the cluster. This shift is also seen in CO₂ adsorption on a negatively charged slab of titania, which resulted in the improved adsorption energy of the carbonate-like structure. For CO₂ adsorption on the negatively charged Cu₅/TiO₂ (Figure 10d), we can see a slightly smaller band gap (Figure 10d), together with higher hybridization of C states with the cluster d orbitals. By analyzing the spin population and net charge of each atom, together with the morphological changes in the cluster shape upon charging the system, we can see that for the charged configuration, CO₂ molecule binds only with the metal cluster, in contrast to the neutral case, in which CO₂ binds to the interface. This change in the adsorption mode is accompanied by a change in the amount of accumulated charge on the CO₂ molecule (from +0.184 e to −0.268 e) upon negatively charging the system. The net spin moment remains 0, whereas the net charge on the cluster increases as a result of the presence of the excess electron. Considering the unpolarized spin configuration of the cluster, we conclude that the net charge of the cluster is actually the amount of charge that it shares with the surface as a result of their interaction. Thus, the improved adsorption energy of the CO₂ molecule on negatively charged Cu₅/TiO₂ is actually due to more hybridization of the CO₂ states with the cluster’s orbitals and also stronger interaction of the complex of cluster + molecule with the support’s surface (considering that the amount of charge shared between the cluster and the support has been increased).

By looking into the bond lengths and angles reported in Table 2, we can see that the bond length elongation and bending of the O−C−O angle in the Ni₅ case are more sensitive to excess charge compared with the Cu₅ case. This agrees with the more stable bent structure of the CO₂ adsorbed on supported Ni₅.

Dissociated CO₂ on TiO₂, Ni₅/TiO₂, and Cu₅/TiO₂. In plasma catalysis, CO₂ dissociation can occur via several reaction paths. In this work, we focus on the adsorption of CO₂ on neutral and negatively charged surfaces and not on the actual reaction paths. Hence, these simulations do not aim to identify the most suitable catalyst for CO₂ dissociation, but they provide more insight into the effect of surface charging, which is one of the characteristic features of plasma catalysis distinguishing it from thermal catalysis. To estimate the effect of charge on the dissociation of CO₂, we examined various initial configurations of dissociated CO₂ (CO(ads) + O(ads)) on TiO₂, Ni₅/TiO₂, and Cu₅/TiO₂.

For CO₂ dissociation on neutral TiO₂, we did not find a stable structure for adsorbed CO(ads). In most cases, CO either desorbs back in the gas phase or attracts an oxygen atom from the surface and so forms a linear CO₂ molecule. We have provided a less stable structure in Figure 11a, in which the CO(ads) + O(ads) phase is achieved. Although results in Figure 12 for dissociation on the bare surface of TiO₂ show an improvement in the adsorption energy due to the presence of the excess electron, dissociative adsorption is thermodynamically unfavorable, regardless of charging. This means that in the absence of a catalyst, dissociation of CO₂ on a bare slab of anatase will not proceed. An interesting parallel can be drawn with the effect of vacancies on the reactivity of TiO₂ toward CO₂ activation. Just like the formation of vacancies, electron addition effectively corresponds to a reduction of the TiO₂ surface. In both cases, this reduction has been found to result in an improved chemisorption of CO₂. However, vacancies additionally provide a strong binding site for oxygen, thus also promoting the dissociation of CO₂ adsorbed on a vacancy; such a site is not created upon charging, and CO₂ splitting remains unfavorable.

By employing Ni₅ as the catalyst, we find a dissociative adsorption energy of −0.03 eV for CO₂ dissociation on the neutral surface (Figure 11c). By adding an excess electron to the system, the adsorption energy significantly increases to −1.85 eV, which makes the reaction thermodynamically highly favorable (Figure 11d).

For the case of neutral Cu₅/TiO₂, dissociation of the CO₂ molecule into adsorbed (CO)ₐds and (O)ₐds is slightly endothermic with an adsorption energy of +0.14 eV (Figure 11e). Upon negatively charging the system (Figure 11f), the dissociative adsorption energy becomes −0.25 eV, making this reaction thermodynamically favorable. Figure 12 shows the corresponding dissociative adsorption energy for each configuration based on DFT and DFT + U calculations.

These results show that the presence of an excess electron has a positive impact on stabilization of the dissociated CO₂. This impact is more pronounced in case of a Ni pentamer as the catalyst, which shows excellent performance in response to the presence of a plasma-induced excess electron and
significantly improves the adsorption energy of both adsorbed and dissociated CO$_2$. Cu$_5$, adsorbed on a neutral TiO$_2$ surface is not active enough to dissociate the CO$_2$ in a favorable way, but it also shows positive feedback to negatively charging the surface. Therefore, these two particular test cases (adsorbed Ni$_5$ and Cu$_5$) are good examples of how electrons from a nonequilibrium plasma can induce a shift in the chemical properties of different catalysts.

Although there are small differences in bond lengths and also adsorption energies in the results obtained from DFT and DFT + $U$, trends regarding the effect of charge on CO$_2$ activation are the same for both approaches. In addition to the comparison between the DFT and DFT + $U$ results, we also investigated the effect of change in the surface charge density. We performed the same calculations for CO$_2$ adsorption on pristine titania by using a larger slab (2 $\times$ 4 supercell) of anatase TiO$_2$(101) corresponding to a surface charge density of $-0.05$ C/m$^2$, which is 2.7 times lesser than that of the small slab. The results indicate that for the large slab, the trends in the effect of charge on stabilization of the bent CO$_2$ molecule remain the same, although less pronounced (see the SI).

## CONCLUSIONS

In this study, we investigated the effect of excess electrons induced by a plasma on the adsorption properties of Ni$_5$ and Cu$_5$ clusters over the anatase TiO$_2$(101) surface and also CO$_2$ activation on both pristine a-TiO$_2$ and supported clusters.

Adsorption of Ni$_5$ and Cu$_5$ clusters on the surface of anatase (101) in the neutral case leads to a charge transfer between the cluster and the support. Depending on the type of catalyst, the direction of charge transfer can be from the surface to the cluster or vice versa. In this case, negatively charging the system leads to minor changes in the stabilization of the clusters. If the excess electron is localized on the surface, it will have a more pronounced impact than when the electron is localized on the cluster. Negatively charging the surface for adsorption of the CO$_2$ on a bare slab of anatase (101) causes the most stable structure of the CO$_2$ molecule to change from a linear to a bent configuration. This is mostly because of the shifting of the high-lying CO$_2$ antibonding $\pi^*$ orbitals toward the valence band, facilitating their hybridization with p or d states of the surface.

In the case of employing Cu$_5$ and Ni$_5$ nanoclusters, the same result is seen for the improvement of bent CO$_2$ stabilization, although the underlying mechanisms are slightly different. Upon negatively charging the system in CO$_2$ adsorption on supported Ni$_5$, the same shift in CO$_2$ high-lying states is seen, which leads to increased hybridization with the cluster d orbitals. In contrast, for the supported Cu$_5$, changing the adsorption site from the interface to the cluster leads to more stabilization of the CO$_2$ molecule. This change in the adsorption mode results in a significant increase in the negative partial charge of the CO$_2$ molecule, which can be considered as indicative for activation of the molecule.43

The dissociation of CO$_2$ on a bare slab of anatase titania is thermodynamically unfavorable, regardless of the added charge. CO$_2$ dissociation is favorable on Cu$_5$ as the catalyst in a charged configuration and on Ni$_5$ both in neutral and charged configurations. Together with better results for adsorption energy and bond elongation of the CO$_2$$_{(ads)}$ in charged configurations, Ni$_5$ could be a good option for plasma catalysis aiming at CO$_2$ conversion.

In general, plasma-induced excess electrons alter the adsorption process by shifting the antibonding states of CO$_2$ toward the valence band, increasing the polarization effects and changing the adsorption site of the molecule. These effects consequently lead to improved stabilization of bent (ads) and dissociated CO$_2$ in negatively charged structures. This can be
considered as a possible reason for the synergistic effects in plasma catalysis.
